Introduction

The gut plays a major role in the whole-body energy equilibrium and human wellness [1-3]. Disruption of gut homeostasis often leads to loss of energy balance with development of life-threatening complications [4]. Intestinal transplantation has evolved from a rare therapeutic modality to a currently life-saving armamentarium for a subset of patients with intestinal failure in whom continuing treatment with intravenous nutrition had become impossible because of end-stage loss of venous access or end-stage liver disease [5].

The field of intestine transplantation is small with only 106 intestine transplants performed in the United States in 2012 at 18 active centers. This represents a decline from a high of 198 intestine transplants in 2007 and a substantially smaller volume compared to all other types of solid organ transplantation [6]. In contrast to the decline in volume in the United States, the volume of intestine transplantation over a 5-year period ending in 2012 increased substantially in South America and Europe. In addition, although the overall volume to date remains less than 50 cases, there has been a substantial increase in the number of centers that have initiated small bowel transplant programs in China and Japan [7]. Due to the small volume of transplants and paucity of centers i.e. only 47 centers worldwide currently active that perform this difficult and rare transplant many individuals outside and even within the medical field are unaware of the indications for intestine transplantation, current outcomes and recent advances [7]. This lack of awareness may have contributed to the decline in the frequency of intestine transplantation in recent years by limiting access to or referral for this lifesaving therapy. Hence, in this narrative review we aimed to recapitulate the current scenario of intestine transplantation including the indications, techniques used, outcomes, major advances, and future prospective on intestinal transplantation.

Brief History of Intestinal Transplantation

The history of intestinal transplantation begins with Alexis Carrel and his description of a method for performing vascular anastomosis. His initial articles demonstrate his bold yet logical approaches to both the technical and theoretical aspects of organ transplantation [8]. Carrel’s technical basis for vascular anastomoses, proposed in 1902, is still valid for all solid organ transplantations, and is based on three main pillars: a) three stitches to change the cylindrical shape of the cut surface of vessels into a triangle; b) everting anastomosis; and c) use of very thin suture needles.

Lillehei et al reported the first canine model of isolated intestinal transplantation in 1959 [9]. This was an important landmark in the modern area of intestinal transplantation, because it was the first time that autographs and allografts were preserved by immersion in iced saline; after orthotopic reimplantation the autographs presented good functional capability. The following year, Starzl and Kaupp described a multivisceral transplantation technique in dogs in which the small bowel was transplanted as a composite of abdominal organs. The grafts included the liver, pancreas, stomach, intestine, and colon. Two central arteries, the celiac axis and the superior mesenteric in continuity with the aorta, were joined to the recipient’s infrarenal aorta [10]. These two studies, along with a small animal experiment by Monchik and Russel, paved the way for investigations of problems related to intestinal transplantation, such as immunology, immunosuppression, graft preservation, metabolic events, and graft function [11].

Indications and Contraindications to Intestinal Transplantation

Indications:

The most common reason for intestinal and multivisceral transplantation is small bowel syndrome which is the leading cause of intestinal failure. Despite the significant improve-
Indications for Intestinal Transplantation

Failure of Parenteral Nutrition
i. Impending (total bilirubin 3–6 mg/dL, progressive thrombocytopenia and progressive splenomegaly) or overt liver failure (portal hypertension, hepatosplenomegaly, hepatic fibrosis or cirrhosis) because of parenteral nutrition–liver injury.
ii. Central venous catheter–related thrombosis of 2 central veins.
iii. Frequent central line sepsis: 2 episodes/year of systemic sepsis secondary to line infections requiring hospitalization; a single episode of line–related fungemia; septic shock or acute respiratory distress syndrome.
iv. Frequent episodes of severe dehydration despite intravenous fluid in addition to parenteral nutrition.

High risk of death attributable to the underlying disease
i. Desmoid tumors associated with familial adenomatous polyposis.
ii. Congenital mucosal disorders (e.g. microvillus atrophy and intestinal epithelial dysplasia).
iii. Ultra–short bowel syndrome (gastrectomy, duodenostomy, residual small bowel 10 cm in infants and 20 cm in adults).

Intestinal failure with high morbidity or low acceptance of parenteral nutrition
i. Intestinal failure with high morbidity (frequent hospitalization, narcotic dependency) or inability to function (e.g. pseudo–obstruction, high output stoma).
ii. Patient’s unwillingness to accept long–term parenteral nutrition (e.g. young patients).

Contraindications:
An active systemic infection, whether bacterial or fungal, poses the most serious threat to survival of the patient in the early postoperative period. The pre-existence of severe neurologic dysfunction and malignancy are obvious preclusions. Individuals with a prior treated malignancy with an appropriate follow-up period, and having been cleared of recurrence by oncological evaluation, should not represent an absolute exclusion. Cardiac dysfunction, acute or chronic, may also be a contraindication; however, a thorough evaluation will determine whether transplantation can proceed safely. The age of the patient is not a usual limitation, however the overall health of the patient, including nutritional status, are of importance in the patient’s ability to tolerate transplantation.

Techniques in Intestinal Transplantation

The type of technique used in intestinal transplantation depends on the underlying etiology of intestinal failure, quality of native organs, presence/severity of liver disease and history of prior abdominal surgeries. Despite the variety of nomenclature in literature, fundamentally there are 4 types of techniques considered while intestinal transplantation. (i) isolated small bowel transplant, (ii) liver-small bowel transplant, (iii) multivisceral transplant, and (iv) modified multivisceral transplant as depicted in Figure 1 [18].

Post-transplant survival rates may be higher for combined liver/intestine recipients compared with isolated intestine recipients due to proven immunologic benefits of the liver [19-21]. However, most patients with small bowel syndrome, pseudo-obstruction and Gardner syndrome receive isolated intestinal or modified multivisceral transplantation [22]. Additionally, recent data have suggested that hepatic fibrosis may not be an absolute contraindication for isolated intestinal transplant as 4 patients with significant portal and centrilobular fibrosis had regression of their liver disease after intestine-only transplant [23].

The technique of intestine alone which typically includes the entire jejunum and ileum as depicted in Figure 2A. Transplantation of the intestine allograft alone as demonstrated in Figure 2B is increasing in frequency and for the first time in 2009 exceeded the number of combined liver and intestine transplants [6].

The most common combination of organs included with the intestine allograft historically was the liver and pancreas; however, the frequency has declined from 68% in 2007 to 39% of all intestine transplants in 2011 [6]. A widely used technique for combined liver, small bowel and pancreas allograft referred by various centers as a multi-visceral graft, composite graft or Omaha technique are to procure all these organs simultaneously from the donor and transplant them en bloc as shown in Figure 3A and B [25]. The advantage of the combined liver, small bowel and pancreas allograft is that no hilar dissection of the graft is needed and therefore, there are fewer risks for donor-related vascular or biliary complications [25]. Alternatively, the liver and intestine can be transplanted as individual organs, without the pancreas graft, which has the advantage that if the intestine allograft should develop severe rejection, it could potentially be removed without requiring re-transplantation of the liver [26].

In some centers, additional gastro intestinal organs including the stomach, duodenum and/or colon may be procured and transplanted in continuity with the intestine allograft without or without donor liver and/or pancreas (Figure 4) [27-30]. Early series had suggested that inclusion of the colon might increase the risk for infection, several recent single center series and a recent review challenge this long held assumption. In fact, inclusion of the colon has been reported in 20% of small bowel grafts over the past decade[7]. Not only has inclusion of the colon been reported to be safe, but it has been associated with a decrease in the water content in the stool leading to fewer episodes of dehydration and fewer hospital readmissions [6, 31, 32]. The inclusion of stomach with the allograft for patients with or without upper abdominal exenteration remains a center-specific decision with some centers applying it universally while others rarely or never including the stomach.
Intestinal Transplantation – Outcomes
Patient and graft survival:
A large series of 500 intestinal transplants demonstrated a direct, significant correlation between advancements in immunosuppression techniques and graft survival [19]. In particular, reduction in graft rejection, infection and renal failure have been credited for the decrease in mortality rates. However, these complications remain prominent and threatening to the long-term survival of graft function. In one study, the persistence of preformed and development of de-novo donor specific antibodies was credited as the most significant risk factor for graft survival [33]. Other significant predictors of long-term patient and graft outcome include personal social support as well as inclusion of liver for visceral allograft longevity. Recently, documented patient survival rates include 90% at 1 year, 75% at 10 years and 61% at 15 years. Overall graft survival rates were 59% and 50% at 10 and 15 years, respectively [34]. Improvements in body mass index and high rates of certified nursing assistant reflect the substantial advancements in the field of intestinal and multivisceral transplantation. In patients who fail to achieve full recovery of allograft motility and function, ischemia reperfusion injury is thought to play a major role, although normothermic ex-vivo perfusion technology may reverse this unwanted effect [35].

Quality of life:
Quality of life has become an essential endpoint for intestinal and multivisceral transplantation. Evidences revealed that non-functional social support and quality of life correlate directly with suboptimal patient survival [36, 37]. Studies that have compared small intestinal transplantation to parenteral nutrition demonstrate that intestinal transplant patients reported significant improvement in quality of life, functional status, decreased anxiety and sleep difficulties compared with patients on parenteral nutrition [38, 39]. In pediatric patients, the child health questionnaire study reported that transplant patients had physical and psychosocial functions comparable to their healthy counterparts. However, a recent study reported lower values in school functioning and psychological health using the Pediatric Quality of Life Inventory instrument [39].

Advancements and Challenges
Since last two decades there has been substantial advancements in improving both graft and patient survival as well as the quality of life of patients who undergo intestinal and mul-
tivisceral transplantation. However, despite these advances, there are still challenges to be addressed are visceral allograft rejection, immunosuppression and immunological monitoring and long-term survivability. Many aspects of intestinal and multivisceral transplantation remains to be defined including biomarkers for early rejection, novel immunologic strategies and methods to reduce infectious complications.

The long-term survivability of both the grafts and the patients are dependent on the development of a multidisciplinary team including social assistance. These endeavours are particularly important for patients with lower socio-economic status and for pediatric recipients to reduce life threatening behaviours’ including substance abuse and noncompliance. Monitoring of graft function, tumor surveillance and effective medical management of comorbidities are critical for sustaining long-term survivability. Furthermore, with studies indicating increased mortality rates in patients on the national waiting list, efforts to modify the existing United Network for Organ Sharing (UNOS)/ Organ Procurement and Transplantation Network (OPTN) allocation system and donor availability should be initiated for intestinal transplantation to further reduce rate of mortality of patients’ with intestinal failure.

Conclusions

Clinical-nutritional autonomy is the ultimate goal of patients with intestinal failure. Outcome improvements in intestinal transplantation have added another dimension to the therapeutic armamentarium in the field of gut rehabilitation through relentless efforts in the standardization of surgical techniques, advancements in immunosuppressive therapies and induction protocols and improvement in postoperative patient care. Improved survival and quality of life as well as resumption of an oral diet should enable intestinal transplantation to be an important option for patients with intestinal failure in addition to continued rehabilitation. We recommend that early referral to intestinal and multivisceral transplantation for patients with intestinal failure will afford them the best opportunity to regain Clinical-nutritional autonomy. Hence, future efforts that use new or existing multisite registries to generate outcome data including measures of quality of life for intestinal failure with and without transplantation should provide answers to questions of timing for intestinal transplantation including preemptive transplant, with less risk of biases inherent to single-center studies. Furthermore, improving expertise in the management of intestinal failure has benefitted all patients including those who receive an intestinal allograft, but it remains essential that referral for transplantation should occur before the clinical problems that motivate referral become so serious that success of the operation is compromised. Future research should focus on detecting biomarkers of early rejection, enhanced immunosuppression protocols, improved postoperative care and early referral to transplant centers.
